We demonstrate a first-order phase transition from non-life to life, defined as non-replicating and replicating systems respectively, and characterize some of its dynamical properties. The model differs from those described previously in that we explicitly couple replicators to their environment through the recycling of a finite supply of resources. We find that the environment plays a central role in defining the dynamics of the transition. The phase transition corresponds to a redistribution of matter in replicators *and their environment*, driven by selection on replicators. In the absence of successfully repartitioning system resources, the transition fails to complete, leading to the possibility of many frustrated trials before life first emerges. The mutual information shared between replicators and environment accurately tracks the progress of the phase transition. The phase transition is marked by a sequence of abrupt transitions whereby replicators become increasingly distinct from their environment. Often, the replicators that nucleate the transition in the non-life phase are not those that are ultimately selected in the life phase. During the phase transition the system experiences an explosive growth in diversity. We discuss the implications of these results for understanding life's emergence and evolutionary transitions more broadly.

INTRODUCTION

Life is a state of matter characterized by a stable pattern of non-equilibrium behavior. Replication, central to maintenance of pattern, is thought to play an important role in driving the transition from non-living to living matter [1, 2]. Numerous theoretical studies have therefore focused on the emergence of the first replicators, including identifying the conditions under which replicators can be selected. Of note is the transition from "pre-life" to "life" observed by Nowak and collaborators, where pre-life is defined as a generative chemistry with no replication, to be contrasted with life, which replicates and evolves [3–5]. By tuning model parameters, a transition is observed where, above a critical replication rate, replicators are selected [3]. Similar features have been noted by Wu *et al.* [6, 7] and others [8]. While several of these studies have discussed the possibility of a phase transition associated with this behavior, the underlying properties of the transition remain to be fully explicated.

In the present study, we demonstrate a spontaneous, first-order phase transition from non-life to life, defined as non-replicating and replicating systems respectively, and establish a central role for the environment in defining the properties of this transition. A prominent feature of prebiotic chemistry, as evidenced by more than sixty years of experiments in prebiotic synthesis, is that it is difficult to abiotically synthesize biomolecules with high yield under early Earth conditions [9]. Accordingly, we regard resource limitation to be a common, and likely important, feature of prebiotic environments. Indeed, previous studies have indicated that finite resources could have been an important factor in *driving* the emergence of life [10–13]. We therefore consider a model prebiotic chemistry with a finite supply of monomers, which must be recycled through polymer degradation to replenish resources available for synthesis of new polymers. We are motivated by empirical evidence that recycling, mediated by coupled polymerization and degradation reactions, may have been an important mechanism driving the early evolution of biopolymers [14–16]. We note that the majority of theoretical models for the emergence of replicators, by contrast, implement reactor flows with a constant flux of monomers into the system and removal of chemical species via dilution (see *e.g.* [2, 3, 6]). The explicit incorporation of non-linear feedback between environment and replicators via degradative recycling presented here therefore distinguishes our computational model from most studied previously.

Due to environmental feedback, the phase transition reported here exhibits features not observable in other models for the emergence of the first replicators. Most notably, the phase transition corresponds to a redistribution of matter in replicators *and the environment*, driven by selection on replicators. The mutual information shared between replicators and environment accurately tracks the progress of the phase transition. The transition has a higher probability to occur when replicators and environment share relatively high mutual information. Selection on the fitness of replicators, including their replicative efficiency and stability as studied here, occurs only in the life phase. The first replicator(s) that appear typically match the bulk composition of their environment. Since the composition of the environment does not in general match that of "fit" replicators (the environment is not fine-tuned for life), the replicators that nucleate the transition in the non-life phase are often not those that are ultimately selected in the life phase. Due to resource constraints the phase transition proceeds through a sequence of abrupt transitions whereby the composition of replicators becomes increasingly distinct from that of their environment. During the phase transition the system experiences an explosive growth in diversity, and concomitantly a massive extinction of extant chemical species to accommodate restructuring driven by the selection on replicators. Extant diversity and the rate of exploration of novel diversity is higher after the transition than before. In the absence of successfully repartitioning system resources, the transition fails to complete, leading to the possibility of many frustrated trials before life first emerges. We discuss the implications of these results for understanding the emergence of life and evolutionary transitions more broadly.

METHODS

Model Description and Motivation

We model the emergence of replicators in an artificial prebiotic chemistry consisting of two monomer types denoted by '0' and '1'. Polymerization occurs via addition of monomers to the end of growing strings. Sequences can degrade into shorter sequences, which can occur at any bond within a given sequence with equal probability. We assume that the inverse process of two short but non-monomeric sequences ligating to produce a longer polymer is sufficiently rare to be neglected. Sequences of length $L \geq r$ can self-replicate. This minimal replicator length approximates a minimal complexity for self-replication in our simplified model. We note that the properties reported here are general and qualitatively similar for any r, where r primarily determines the relative timescale for discovering replicators, and thus for the phase transition to occur (described below). In this study, we set $r = 7$, such that the appearance of the first replicators is rare, but not so rare that we never observe it [6]. We expect that changing r will change the timescale of the transition but will not qualitatively effect the results presented here.

In the absence of an imposed fitness landscape (defined below), the properties of our chemistry are fully specified by the rate constants k_p, k_d and k_r for polymerization, degradation and replication, respectively. We regard these parameters, along with the abundances of '0' and '1' monomers, as fully specifying the prebiotic environment in our model chemistry. Thus, for example, a difference in temperature defining two different prebiotic environments would correspond in our system to simulations conducted with two different k_d values, that is, if temperature affects the degradation rate of polymers for the particular chemistry of interest (*e.g.* which might perhaps depend on the backbone chemistry of biopolymers, see [12] for discussion).

Since we are interested in the dynamics of replication in this work, and specifically the transition from non-life to life, we do not include the effects of mutation, which is well known to play an important role in evolution once life has already emerged. Therefore a simplification in our model is that replication only functions to copy extant sequences, and does not produce any novelty. Novelty is introduced through the prebiotic processes of polymerization and degradation. As long as mutations also obey the principles of resource constraints, we expect that their primary effect would be to increase the search rate for replicator(s) that match their environment, which, as we discuss below, nucleates the phase transition described here.

Simulations were implemented using a kinetic Monte Carlo algorithm [17, 18]. For more detailed discussion of the implementation of that algorithm in prebiotic recycling chemistries we refer the reader to [12] or [15]. In what follows, the polymerization, degradation, and replication rate constants were set to $k_p = 0.0005, k_d = 0.5000$, and $k_r = 0.0050$ respectively, and the system was initialized with 500 monomers each of '0' and '1' with no polymers present, unless otherwise noted. It is important to note that since this is a closed system, the initial conditions specify the bulk composition of the system for all time.

Two Fitness Landscapes: Static and Dynamic

To explicitly couple the properties of replicators to that of their environment, we model the fitness of replicators as determined by two factors:

1. a *static* fitness associated with a trade-off between stability and replicative efficiency intrinsic to individual replicators , and

2. a *dynamic* fitness associated with resource availability in the environment .

The first introduces a non-dynamic component of the fitness landscape associated with the properties of individual replicators that is a common feature of origin of life models. The latter environmentally-dictated fitness is dynamic and a unique feature of the resource-dependent replication model presented here (see also [12] or [15]).

Static Fitness. The trade-off between stability and replicative efficiency of sequences captures features of nucleic acid systems believed to play an important role in early evolution—in particular that molecules that fold well are typically not good templates and conversely that good templates often do not fold well and are thus less resistant to degradation [19, 20]. The mathematical form this trade-off implemented here is inspired by that of [19], in that we encode both the stability and replicative efficiency of replicators utilizing a sigmoid function:

$$f(n) = 0.5 + \frac{n^2}{2(10+n^2)}. \tag{1}$$

The replicative fitness of a sequence x_i with length L is quantified by scaling its replication rate by $1 + f(zeros(x_i))$. Similarly, the stability of sequence x_i is determined by scaling the degradation rate by $1 - f(ones(x_i))$. Thus, for sequences of a given length $L \geq 7$, the homogeneous string of '1's is the most stable sequence of that length, the homogeneous string of '0's is the fastest replicator, and sequences with a roughly equal number of '0's and '1's best balance stability with replicative efficiency. This landscape is constructed to reflect two features we regard as important to the generally unknown shape of biopolymer fitness landscapes: the fittest sequences are much rarer than less fit sequences and their composition is not necessarily reflective of the bulk composition of their environment. Sequences with $L < 7$ do not replicate, so only the stability landscape is relevant for short sequences. This trade-off establishes a fitness landscape intrinsic to a polymer's specific sequence composition that is fixed within a given environmental context.

Dynamic Fitness. Replication rates are also dynamically determined by the availability of free monomers in the environment. The replication rate for sequence x_i is weighted by a factor $\sum_{n_i}^{L-1} y_{n_i} y_{n_i+1}$, where y_n is the abundance of the monomer species at position n in sequence x_i. This term yields a resource-dependent replication rate that is also sequence dependent, similar to that implemented by one of us (SIW) in [15] where analogous dynamics to the phase transition reported herein were observed, although not characterized as such. The functional form of the resource dependence is an approximation intended to model nucleation of the first bond formed on a template as the rate-limiting step, while simultaneously capturing sequence information by summing over all possible nucleation events on the template, as introduced in [15]. Thus, in our model the replication rate of a given sequence x_i depends in part on how well its sequence composition matches the relative abundances of '0' and '1' monomers in the environment. Since the abundances of '0' and '1' monomers change over time as monomers are consumed via polymerization and replication and generated via degradation, this creates an environmentally dictated fitness landscape that is a central feature of any resource-constrained dynamics. We expect qualitative features of the dynamics observed here to be a general feature of sequence-specific resource-dependent replication that does not depend specifically on the form of dynamic landscape chosen for this study and will be qualitatively similar for other replicator models where stoichiometry plays a role in setting the efficiency of replication.

Mutual Information as a Measure of the Transition from Non-life to Life

To characterize the dynamics of the phase transition, we employ mutual information, a common tool in information theory, which measures the mutual dependence of two variables within a dynamic time series. Most often, mutual information is calculated on time series data. Herein, we explicitly measure the mutual information between two variables *as a time-series variable* itself to track the progress of the phase transition from non-life to life. To generate a time series for mutual information we use the *pointwise mutual information*, $\mathcal{P}$. Given two random variables $X = \{x_1, x_2 ... x_n\}$ and $Y = \{y_1, y_2 .... y_m\}$, $\mathcal{P}$ is quantified as:

$$\mathcal{P}(x_i : y_i) = \log \frac{p(x_i, y_i)}{p(x_i)p(y_i)}. \tag{2}$$

[21], where $p(x_i)$ and $p(y_i)$ are the probabilities of observing the event where X is in state x_i and Y is in state y_i, respectively, and $p(x_i, y_i)$ is the joint probability of this event occuring. We generated probability distributions by counting the frequency of a given event (*e.g.* abundance of '0' and '1' monomers and of replicators of a given sequence composition) in our time series data. In the results presented here, the distributions were generated using time series data from an ensemble of 100

experimental runs over $10,000$ time steps each. To ensure that the frequency based probability distributions were not biased by counting states from different phases of the system (see below), the frequencies were generated from data that sampled equally from both phases. The probabilities of different states therefore represent ensemble statistics which do not depend on time, while the particular ordering of states in a time series is used to determine the time series $\mathcal{P}$. In principle, $\mathcal{P}(x_i : y_i)$ can be calculated at every time step. However, in stochastic systems, such as ours, $\mathcal{P}$ will fluctuate rapidly in time and is unlikely to yield useful insights. We therefore sum $\mathcal{P}$ over a fixed time window to yield the mutual information for that window. Explicitly, for a window size of w, the mutual information at time t is defined as the average of $\mathcal{P}(x_i : y_i)$, and is given by:

$$\mathcal{I}(X(t) : Y(t)) = \sum_{i=t-(w/2)}^{t+(w/2)} p(x_i, y_i) \log \frac{p(x_i, y_i)}{p(x_i)p(y_i)} \; . \quad (3)$$

[22]. This value will depend on time, not because the probabilities of different states will depend on time, but rather the realization of different states is time ordered. Determining an appropriate size for w is important. If w is too large, the entire measurement collapses into one value yielding no insights into how the system is evolving in time. By contrast, if w is too small, fluctuations wash out interesting larger scale structure.

In our system, mutual information was measured between R and E which are ordered pairs that track the number of zeros and number of ones in both replicators (R) and in free monomers in the environment (E). We chose w heuristically, such that the value of $\mathcal{I}(R; E)$, tracking the mutual information between replicators and environment, was relatively constant but large fluctuations could still be resolved. For the results presented $w = 100\Delta t$, where $\Delta t = 0.1k_h^{-1}$ is the the resolution of the time series data in natural units. We note that different values of w change the results quantitatively, but not qualitatively: the system still maintains a non-zero value of the mutual information in the non-life phase which tends toward zero in the life phase (discussed below).

RESULTS

Non-life and Life

Two long-lived states are observed in our model: "non-life" and "life", which are dominated by polymerization and replication, respectively. While the non-life phase here shares features in common with "pre-life" as previously characterized [3], it also has some striking differences. We therefore use "non-life" rather than "pre-life" as it does not imply life will inevitably emerge since in our system many transitions fail to complete.

In the non-life phase, long sequences are exponentially rare, and the majority of system mass is in monomers and dimers (not shown). Sequences of all lengths have relatively similar composition, as shown in Fig. 1. The composition of extant polymers is reflective of the abiotic availability of resources and the stability landscape established by Eq. 1. In contrast to other models [3, 7, 8], here *replicators exist in the non-life phase*, albeit at exponentially low abundance. However, selection on replication cannot overcome environmental constraints. Replicators in non-life are not the most fit in terms of stability or replicative efficiency (*e.g.* homogenous '0' or '1' sequences, respectively) but instead are predominately heterogenous with compositions determined by the bulk distribution of resources (right, top panel in Fig. 1).

In the life phase, the symmetry of the environment, constituting an equal number of '0' and '1' monomers, is broken in the composition of replicators due to selection on the static fitness landscape, a feature which is not observed for non-life (compare $L = 7$ compositions, Fig. 1). In the life phase, replicators are primarily homogeneous '1's or '0's. The asymmetry imposed by selection on replicators is exported to shorter sequences, which have the opposite compositional signature than that of the replicators. The compositional reversal is seen only below $L = 6$. Although $L = 6$ sequences cannot replicate, they are formed primarily via degradation of $L = 7$ replicators and thus their formation is dominated by templated assembly. In the life phase, we observe that replicators are selected based on their intrinsic fitness and not strictly their composition. The defining feature of the life phase is therefore not necessarily the presence of replicators, which exist in both phases. Instead, *the defining characteristic of "life" in this model is that the distribution of resources is dictated by selection on the properties of replicators.*

A First Order Phase Transition from Non-life to Life

For fixed values of k_p, k_d and k_r, the system exhibits a spontaneous and abrupt phase transition from non-life to life (no external tuning), as shown in Fig. 2. The time of transition is exponentially distributed (not shown), indicative that the transition is first order [23]. Often there are many frustrated transitions prior to a successful phase transition (top, Fig. 2). The frequency that the transition will occur is dependent on how well the composition of the replicator(s) matches the environment (bottom, Fig. 2). This result is distinct from other models that do not account for environmental feedback [3, 6] – here the transition is *not* coincident with the first 'discovery' of a sequence capable of replication, since replicators exist in non-life. Instead, the transition occurs when the dynamic fitness of replicators is high, as occurs when the composition of replicators and environment synchronize

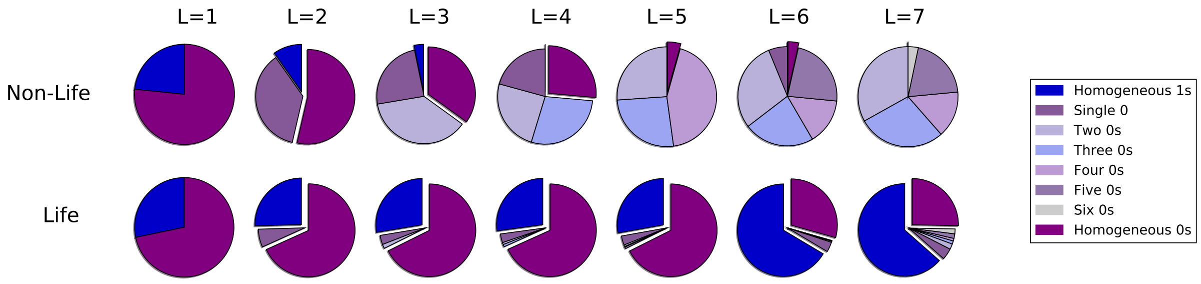

FIG. 1. Ensemble averaged compositions of all sequences with $L \leq 7$. The distributions in the top-panel characterize the non-life phase, and the bottom-panel characterize the life phase. Data is averaged over 100 simulations.

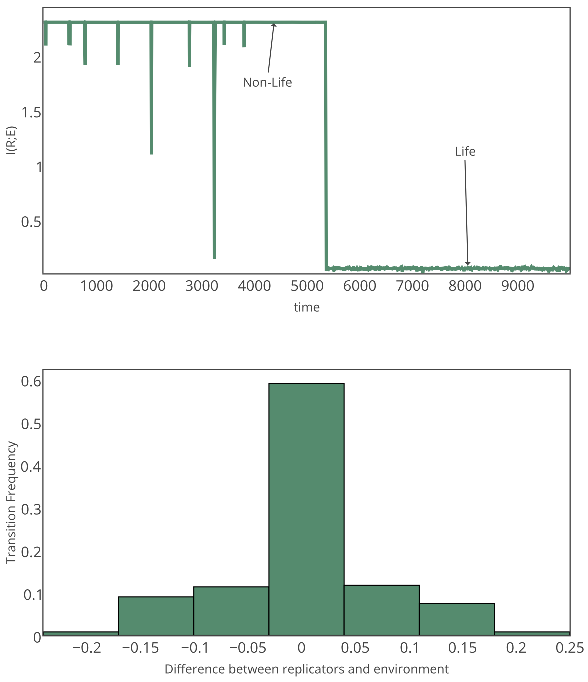

FIG. 2. Top: Time series showing the mutual information between extant replicator composition and the environment. The phase transition is clearly evident in the abrupt shift from $\mathcal{I}(R;E) \sim 2.5$ in the non-life phase to $\mathcal{I}(R;E) \sim 0$ in the life phase at $t \sim 5500$. Also evident are several failed transitions, including one that nearly runs to completion before reverting back to the non-life phase near $t \sim 3000$. Bottom: The frequency of successful phase transitions plotted against the difference between the distribution of free monomers and replicator composition, for an ensemble statistic of 256 simulations.

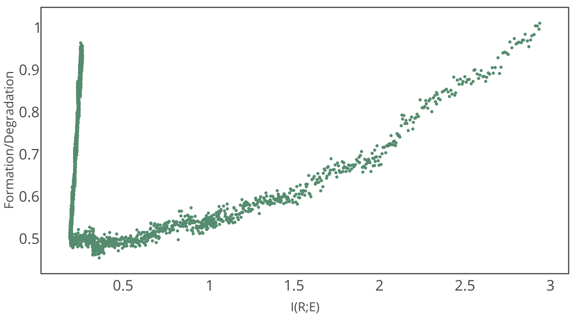

FIG. 3. Phase trajectory for an ensemble of 100 systems transitioning from non-life to life, moving from left to right. Axes are the mutual information $\mathcal{I}(R;E)$ between replicators and environment (x axis) and the ratio of formation (polymerization and replication) to degradation rates (y axis).

their composition. In our example, since both monomer species are equally abundant in the initial distribution of resources, the nucleation event is typically mediated by heterogeneous replicator(s) composed of a roughly equal number of ‘0’s and ‘1’s. These are not the sequences that are ultimately selected in the life phase, which include the homogeneous, fit sequences. Thus, in resource-limited models like ours, the replicator(s) that nucleates the transition will often not be that which is ultimately selected.

However, just as in models without resource restrictions, selection ultimately leads to the fixation of fit sequences. The transition is accurately tracked by measuring the mutual information $\mathcal{I}(R;E)$ between the composition of extant replicators and free monomer resources (top panel, Fig. 2). Prior to the transition, replicators and monomers share a high degree of mutual information and the composition of replicators generally matches that of their environment. However, once life emerges and selection reconstitutes the allocation of resources, replicators no longer match the information content of the environment and $\mathcal{I}(R;E) \rightarrow 0$ with small fluctuations. This behavior clearly illustrates how environmental (dynamic) selection, with a high degree of mutual information between environment and replicators dominates in the non-life phase, whereas functional (static) selection, which is not dependent on the information content of the environment, dominates in the life phase.

An interesting feature of this phase transition is that, due to resource constraints, the selection of replicators

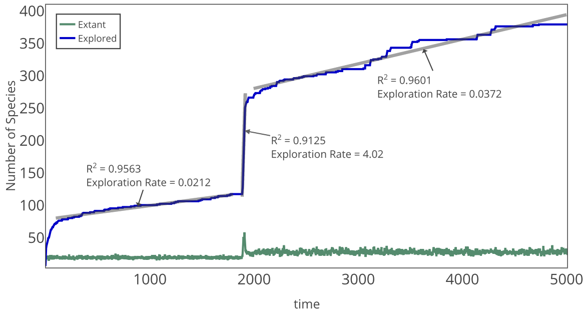

FIG. 4. Time series for the extant species population size and total number of sequences explored by the system. Linear fits to the explored species are shown. The exploration rate is 75% faster during the life phase compared to the non- life phase, and is 2 orders of magnitude larger during the transition.

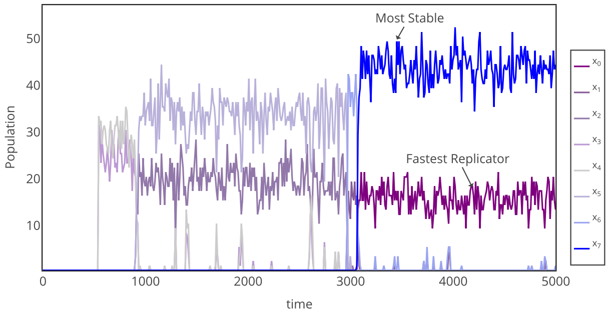

FIG. 5. Series of symmetry breaking transitions in the selection of fit, homogeneous '0' and '1' length $L = 7$ replicators. Here, the subscript denotes the number of '1' monomers in the sequence (*e.g.* x_0 contains no '1's, x_1 bins all polymers with a single '1' monomer in their sequence, and x_7 contains all '1's). Parameters are $k_p = 0.0005, k_d = 0.9000$, and $k_r = 1.000$.

coincides with dynamic restructuring of the environment (including both monomer and non-replicating ($L < 7$) sequence populations, see *e.g.* Fig. 1). Fig. 3 shows an ensemble averaged phase space trajectory through this restructuring, which shows that the phase transition moving from non-life to life equilibria is highly unstable and dominated by degradation. In both the non-life and life phases, polymer formation rates (polymerization and replication) balance rates for polymer degradation, with ratios of formation/degradation ~ 1. However, the life and non-life phases are clearly distinguished in phase space by very different values for the mutual information, $\mathcal{I}(R;E)$: $\mathcal{I}(R;E) \sim 3.0$ for non-life and $\mathcal{I}(R;E) \sim 0.25$ for life, for results in Fig. 3 (see also time series with different model parameters, top Fig. 2). The rampant degradation through the phase transition results in a rapid and dramatic restructuring of the extant polymer population and a steep slope in the rate of sequence exploration, as observed in Fig. 4. The extant diversity and the rate of introduction of new sequences are both higher in the life phase than the non-life phase (Fig. 4), attributable to the higher turnover rate of resources in the life phase (due to the higher assembly rate of polymers via replication).

Shown in Fig. 5 is the time evolution for all sequences with $L = 7$, binned by sequence composition, for a set of parameters where the transition is prolonged enough to resolve details of the restructuring. Resources constraints enforce selection of sequences in complementary pairs that maintain the symmetry of the bulk resource distribution of the environment (50% '0's and 50% '1's). The system subsequently undergoes a series of abrupt transitions associated with increasing sequence homogeneity, where replicator composition increasingly breaks the symmetries imposed by the environment. The asymmetry introduced by replicators is exported to their environment, as evidenced by the compositions of shorter sequences $L < 7$ and the distribution of monomers (see *e.g.* Fig. 1).

The Timescale for Life's Emergence

The phase transition from non-life to life described here is a robust feature of the dynamics, observed over a large range of parameters values with qualitatively similar features. Quantitative differences arise in the final abundances of replicators and in the timescale for the transition to occur, which are both sensitive to the specific details of the prebiotic chemistry under consideration. Fig. 6 shows the average time to complete the phase transition as a function of the degradation and replication rate constants, k_d and k_r, which as noted earlier may be viewed as specifying different environmental contexts within which life might emerge. For the results presented, the transition was identified as complete when 75% of the total replicating mass was allocated in homogeneous (fit) sequences.

One might *a priori* expect the transition to be most rapid (favored) for fast replication (high k_r) and slow degradation (low k_d), however this is not what is observed. For high degradation rate $k_d = 5.0$, the time to the transition is largely independent of k_r (top panel, Fig. 6). Lowering the degradation rate ($k_d = 1.0$ and $k_d = 0.5$, bottom two panels in Fig. 6) increases the dependence of the transition time on k_r, which, on average, occurs most rapidly for relatively low k_r. This counterintuitive behavior arises as a result of the resource constraints. For high degradation rates, there is a high rate of turnover increasing the likelihood of discovering functionally fit sequences, but the probability of survival is low, so the transition time is long regardless of replicative efficiency. For lower degradation rates, high replication rates lock resources in less fit sequences, frustrating the system's restructuring, also leading to long transition times.

The rate of degradative recycling seems to be the primary factor in determining the transition timescale. Fig. 7 shows the transition time observed for different abiotic resources abundances, quantified by the ratio R of the total number of '1' monomers to total system mass. The transition timescale is not expected to be symmetric with respect to the relative abundance of '0' and '1' monomers. For large values of R (environments rich in '0' monomers that confer stability), where recycling is inherently slower, the average transition time may be much longer than in environments with fewer stable polymers. Our data supports this expectation although the variation in transition times is large. These features suggest that environments which engender degradative recycling at a moderate rate may be the most conducive to nucleating the origin of life under resource-limited conditions.

Hysteresis and Life as a Phase of Matter

To further illustrate the distinction between the non-life and life phases we can study hysteresis effects. In the study of traditional physical phase transitions, particularly in materials, hysteresis is a common phenomena [24] and occurs when characteristic quantities (in this case mass in homogeneous "fit" replicators), depend on the current state and history of the system [24]. Fig. 8 shows a hysteresis diagram for the transition between the non-life and life phases in our model. Here the system is identified as being in the life phase if the homogeneous replicators (*i.e.* functionally fit replicators) represent more than 75 % of the total replicating mass. For the parameters presented in Fig. 8 the system can be in either the life phases or the non-life phase, however it is very sensitive to changes in the degradation rate. Holding other parameters fixed and increasing the degradation rate takes the system to a regime where the life state is unstable and will transition to the non-life state spontaneously. In green (top) the system was initialized at $k_d = 0.1$ in the life phase. The value of k_d was then slowly increased (by 0.00001 per unit time), until the life phase became unstable and the system transitioned into non-life. In blue (bottom) is exactly the opposite, the system was initialized in non-life and the value of k_d was decreased (again by 0.00001 per unit time) until the system transitioned into the life phase. For the parameters in this example, the non-life phase can persist even when there is a substantially large number of replicators in the system, *i.e.* as occurs when the majority of "replicators" are synthesized via polymerization, and the fit (homogeneous) replicators do not dominate the resource distribution. Thus the system can transition from life to non-life, distinguished purely by whether or not their is

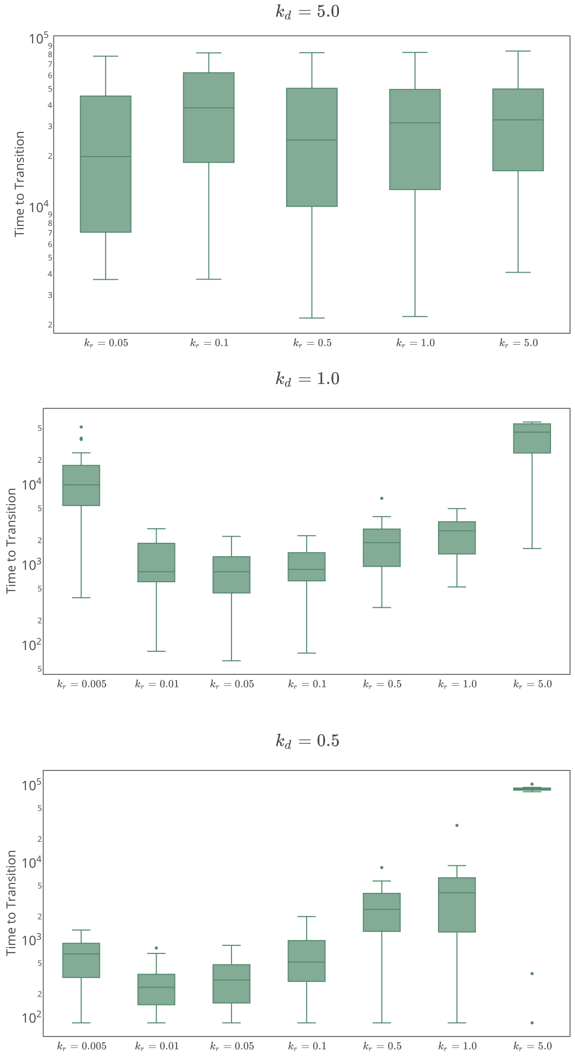

FIG. 6. Timescale for completing the phase transition as a function of reaction rate constants for degradative recycling k_d and replication k_r. Data from 25 simulations is shown, all data points are included in the box and whisker plots. The center line for each distribution is the median, the boxes contain half the data points and the bars show the range.

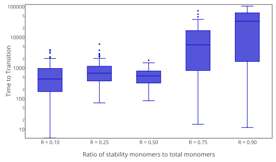

FIG. 7. Timescale for completing the phase transition as a function of the abiotic distribution of resources. Here, the parameter R is the ratio of '1' monomers (which confer stability) to total system mass. Data from over 100 simulations is shown, all data points are included in the box and whisker plots. The center line for each distribution is the median, the boxes contain half the data points and the bars show the range.

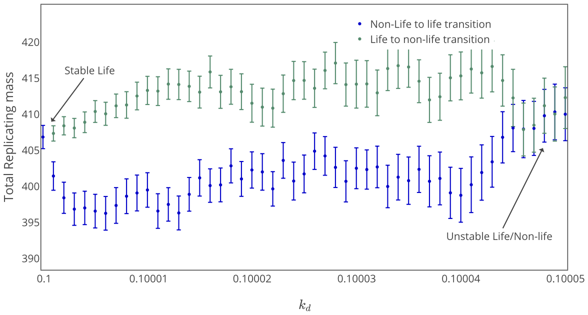

FIG. 8. Hysteresis diagram following the transition from life to non-life and back to life. Rate constants are $k_p = 0.0005$ and $k_r = 0.001$ with the degradation rate slowly adjusted in steps of $k_d = 0.00001$ per unit time to modulate the hysteresis effect.

selection on the properties of replicators.

DISCUSSION

We have demonstrated the existence of a spontaneous, first order phase transition from non-life to life that demonstrates many features not previously observed, which arise due to explicit incorporation of environmental feedback. It might be argued that the dynamics reported here do not represent a true phase transition. In the study of equilibrium physical systems, free energy is the quantity which is minimized to determine the state of the system [23]. Typically, this involves a play-off between minimizing total energy and maximizing entropy. When these two favor different results, a system is expected to exhibit a first order phase transition from order to disorder. Here, in our dynamical scenario, a similar tradeoff happens between two processes that consume and try to minimize the number of free monomers (which may be related to the minimization of free energy [25]). These two different ways—*viz.,* maximizing the number of bonds via polymerization, or by maximizing the number of polymers via replication—yield distinct results with a sharp boundary between them, which motivates the classification of the observed dynamics as a phase transition.

Due to the explicit coupling between replicators and environment, the phase transition reported here displays many features one might expect for a newly emergent biosphere that are not observable in open-flow reactor models. In particular, restructuring during the phase transition drives a vast increase in extant diversity and in the rate of exploration of novel diversity. This indicates that the emergence of life should coincide with an explosive growth of novelty in resource limited systems. Concomitantly, during the phase transition the system is dramatically restructured, indicating that the emergence of life should have significantly altered the environment of the early Earth. It is well known that biology alters its environment over generational and geological timescales, and that the presence of life defines many features of the Earth-system. It is interesting to observe this as a generic feature of life, characteristic of life as a phase of matter from its first inception, even in an abstract and simplistic model as presented here. In fact, we observe that if replicators do not transform their environment to enable their selection, the phase transition fails to complete. The model therefore includes the possibility of many frustrated trials before life first emerged (see *e.g.* Fig. 2), with success entailing a transformation of the environment as a necessary component of the process of biogenesis. These features indicate that it should be difficult to retrace the precise history of the origin of life: the replicators that are ultimately selected will, in general, neither be reflective of the ancient planetary environment nor be representative of the replicators that first nucleate the phase transition. Thus, in general the conditions favoring the emergence of life may not be the same as those favoring its subsequent evolution.

Interestingly, the features characteristic of the phase transition are heavily dependent on degradative recycling of finite resources. This suggests new perspectives regarding the role of degradation in the origin of life, which is typically viewed as an impediment in prebiotic chemistry, rather than a process central to early evolution [26]. Cast under new light in the resource-constrained dynamics observed here, it is perhaps not a coincidence that RNA, as a biopolymer that played a prominent role in early evolution, is highly susceptible to hydrolysis, perhaps resolving an apparent paradox in the origin of life[27]. The properties of this phase transition are in principle testable in the laboratory in experimental systems that permit recycling of biopolymers, for example as reported in [15]. In particular, the observed dynamics should place further constraints on the kinds of chemistries (defined by relative rates k_d, k_r and k_p and resources abundances) that are most conducive to mediating the transition to living matter (see also *e.g.* [28]).

Importantly, the most distinctive feature of the life phase in our model is not necessarily the presence of replicators, since these also exist in non-life. Instead it is *selection* on the properties of replicators, such as replicative efficiency and stability in the example presented here. Selection in turn necessitates a redistribution of matter due to resources constraints. This restructuring is coincident with a sharp transition in the mutual information between the composition of replicators and the distribution of free monomers, which accurately tracks the phase transition. Previous work connecting information theory to life's origins reported that the probability to discover a self-replicator by chance should depend exponentially on the availability of its composite monomers [29]. Our results demonstrate an additional necessary feature is that, in the case of resource constrained replication, replicators and environment synchronize their composition (share high mutual information). Such synchronization enables exponential growth of the replicator population based on high dynamic fitness, which in turn enables selection on the properties of new replicators discovered. When these replicators do not match the bulk composition of the system, they force restructuring to accommodate their selection. We further note that very few measures have been proposed to explicitly quantify the origin of life transition. Here, mutual information between replicators and environment accurately measures the progress of the phase transition reported, perhaps acting as an order parameter. Future work should identify how broadly applicable this approach is, by applying mutual information to other candidate scenarios for the origin of life, such as in the formation of autocatalytic sets.

We have identified replicators with "life" in this simple model. However, the definition of life is an important open philosophical and scientific question [30]. The observed information-theoretic properties of this transition are consistent with proposals that life is most defined by its informational properties [31] (here, replicators might be interpreted as driving the dynamics of the entire system in a "top-down" manner due to adaptive selection [32]). The life phase may be interpreted a state where the kinetics of individual replicators (*e.g.* as quantified by their replicative efficiency and stability) dictate the behavior of the entire system, consistent with the notion that life is a kinetically driven state of matter [8]. Although our motivation is to understand the origin of life utilizing this model system, we note that the model is sufficiently abstract to capture features that may be universal to a broader class of evolutionary transitions. In particular, the dynamics could be universally characteristic of the discovery of novel, selectable patterns in the distribution of resources among replicating populations. For example, the abrupt nature of the transition shares features in common with punctuated equilibrium [33]. The dynamics of this phase transition also demonstrate behavior that may be characteristic to mass extinctions: the system's restructuring necessitates a period of instability driven by rampant destruction of extant diversity, which is followed by an explosion in novel diversity. The relationship to the phase transition reported here could be tested, for example, by analyzing the connection between resource distribution patterns and abrupt evolutionary transitions.

Finally, we point out that from the perspective of stably propagating informational patterns (replicators) that are decoupled from those imposed by the bulk environment, simple replicators such as those presented here may not be the most effective architecture for a self-reproducing system. In this model, the total composition of the system remains fixed, what life does is restructure the distribution of matter within the system, due to the propagation of selectable replicating resource allocation patterns. An interesting open question is how this phase transition might play out for more life-like replicative systems, such as those with the architecture of a von Neumann self-reproducing automata [31, 34, 35], a subject we leave to future work.

This project/publication was made possible through support of a grant from Templeton World Charity Foundation. The opinions expressed in this publication are those of the author(s) and do not necessarily reflect the views of Templeton World Charity Foundation. The authors wish to thank Paul C.W. Davies and Nigel Goldenfeld for constructive conversations on this work and the Aspen Center for Physics (supported in part by the National Science Foundation under grant no. PHY-1066293) for hosting SIW and TB, where the initial seeds of the idea that nucleated this project were matched with the right environment.
